12 **Abstract**

13 Precambrian banded iron formations (BIFs) represent an important source of mineable  
14 iron, as well as an archive recording secular changes in the chemistry of the Earth's early  
15 oceans. Here we report petrographic and geochemical characteristics of unweathered drill core  
16 samples from the Bikoula BIF, a virtually uncharacterized oxide facies iron formation, hosted  
17 in the Mesoarchean Ntem complex, southern Cameroon. The BIF is cross-cut with syenitic  
18 veins. The entire succession is highly deformed and metamorphosed under granulite facies  
19 conditions. The BIF is characterized by alternating micro-bands of magnetite, quartz and  
20 pyroxene. Sulfides (pyrite, pyrrhotite, and chalcopyrite), oligoclase, ferro-pargasite, biotite and  
21 ilmenite occur as minor phases. The presence of pyroxene, ferro-pargasite and oligoclase,  
22 relatively high contents of major elements such as Al<sub>2</sub>O<sub>3</sub> (0.76 – 7.52 wt.%), CaO (1.95 – 4.90

23 wt.%), MgO (3.78 – 5.59 wt.%), as well as positive correlations among Al<sub>2</sub>O<sub>3</sub>, TiO<sub>2</sub>, HFSEs,  
24 LILEs and transition metals (V, Cr, Ni, Cu and Zn), suggest that the BIF protolith included a  
25 significant amount of clastic material. Several samples have preserved seawater-like PAAS-  
26 normalized REE-Y patterns, including LREE depletion, and positive La and Y anomalies.  
27 Positive Eu anomalies observed in some of the analyzed samples indicate influx of  
28 hydrothermal fluids (possibly including Fe and Si) within the basin where the BIF precipitated.  
29 However, few samples show unusual negative Eu anomalies that likely result from a large  
30 proportion of clastic contamination. The lack of Ce anomalies suggests that the Bikoula BIF  
31 was deposited in a basin that was (at least partly) anoxic or suboxic, where it was possible to  
32 transport and concentrate dissolved Fe<sup>2+</sup>.

34 fluids; Seawater

## 35 **1. Introduction**

36 Banded iron formations (BIFs) are chemical sedimentary rocks that contain  $\geq 15\%$  iron  
37 and typically display banding consisting of iron-rich layers alternating with silica-rich layers  
38 (James, 1954; Trendall, 2002). BIFs are common in the Precambrian geological record, while  
39 an equivalent facies has never been observed in Phanerozoic sequences or modern  
40 environments (Klein, 2005). BIFs are of great interest due to their economic importance as the  
41 world's largest source of iron ore (Robb, 2005), and because the models proposed to explain  
42 their genesis are intimately linked to the evolution of the Earth's atmosphere, hydrosphere, and  
43 biosphere (Konhauser et al., 2009; Bontognali et al., 2013). Based on their depositional  
44 environment and co-occurring rock facies, BIFs have been subdivided into Superior- and  
45 Algoma-types (Gross, 1980). The former were deposited in near-shore continental shelf  
46 environments and are associated with carbonates, quartzites and black shales, whereas the latter

47 are consistently associated with volcanic rocks and greywackes in greenstone belts. All BIFs  
48 have experienced some form of diagenetic and/or metamorphic overprinting (Klein, 2005),  
49 which makes it challenging to unambiguously reconstruct the precise depositional setting and  
50 the paleoenvironment in which the iron-bearing minerals originally precipitated.

51 Despite decades of research, many fundamental questions about the origin of BIFs  
52 remain unanswered and highly debated. However, some common concepts recur in most of the  
53 proposed hypotheses. It is commonly thought that, during the period of BIFs deposition, the  
54 oceans (at least at depth) were anoxic, and thus capable of transporting and accumulating  
55 dissolved ferrous iron (Cloud, 1968; Holland, 1973). The latter may have been oxidized to  
56 solid-phase iron oxyhydroxides through either biological (oxygenic or anoxygenic  
57 photosynthesis) or nonbiological (ultraviolet photo-oxidation) processes (Bekker et al., 2014).  
58 Alternatively, direct precipitation under anoxic conditions may have formed Fe-carbonates or  
59 mixed valence Fe-silicates. Based on REE distributions, it has been proposed that Fe and Si in  
60 most BIFs derive from hydrothermal sources (Holland, 1973; Bau and Möller, 1993; Morris  
61 and Horwitz, 1983), although Hamade et al. (2003) used Ge/Si ratios in BIFs to postulate a  
62 continental source for silica.

63 This study focuses on the Bikoula BIF, an Algoma-type iron formation hosted in the  
64 Mesoarchean Ntem complex, which constitutes the northwestern edge of the Congo craton  
65 (Maurizot et al., 1986). Several greenstone belt occurrences hosting BIFs of economic  
66 importance have been identified in the Ntem complex (Maurizot et al., 1986). However,  
67 previous studies of BIFs in this region exclusively focused on weathered BIFs that crop out at  
68 the surface (Lerouge et al., 2006; Suh et al., 2008, 2009; Nforba et al., 2011; Ilouga et al., 2013;  
69 Chombong et al., 2013; Anderson et al., 2014; Ganno et al., 2015, 2016), where weathering  
70 makes it difficult to reliably understand their petrogenesis. Here, we present the first  
71 petrographic and geochemical data on unweathered BIF and cross-cutting rocks of the Ntem

72 complex, which were collected in the framework of a drilling project named the Bikoula Iron  
73 Ore Project (Aluvance Plc, 2014). The presented data are compared, discussed and interpreted  
74 with regard to previous studies of BIFs.

## 75 **2. Geological setting**

### 76 **2.1. Regional geology**

77 The Ntem complex corresponds to the northwestern border of the Congo craton in  
78 Southern Cameroon (Maurizot et al., 1986). It is bounded to the north by the Yaoundé Group  
79 which belongs to the Pan-African orogenic belt in Central Africa (Nédélec et al., 1986; Nzenti  
80 et al., 1988). The Ntem complex has been subdivided into three units: Ntem, Nyong and Ayna.

81 The Ntem unit contains the Bikoula BIF (Fig. 1) and comprises an intrusive series, a  
82 banded series and greenstone belts (Maurizot et al., 1986; Pouclet et al., 2007). The intrusive  
83 series occurs in the northern part and consists dominantly of magmatic charnockitic suite and  
84 TTG (Tonalite-Trondjemite-Granodiorite) suite (Pouclet et al., 2007). The banded series is  
85 represented by highly deformed granulitic gneisses (leptynites, enderbergites, granitic gneisses  
86 and charnockitic gneisses) that are distributed over the southern part of the Ntem unit (Maurizot  
87 et al., 1986; Takam et al., 2009).

88 Greenstones in the Ntem unit occur as disrupted belts and as xenoliths in the intrusive  
89 series, indicating an older age for their formation (Shang et al., 2004a, 2007). These supracrustal  
90 rocks consist of BIFs, metagraywackes, sillimanite-bearing paragneisses, garnet-bearing  
91 amphibolites and pyroxenites (Shang et al., 2004a; Tchameni et al., 2010). They were affected  
92 by granulite-facies metamorphism with estimated peak temperatures of  $750 \pm 50$  °C at 5 – 6  
93 kbar (Tchameni, 1997; Tchameni et al., 2001). Emplacement of the greenstone belts in the Ntem  
94 unit has been dated at ca. 3.1 Ga using the Pb-Pb zircon evaporation technique (Tchameni et

95 al., 2004). Greenstone belts are highly dismembered and cross-cut by late syenitic plutons and  
96 doleritic veins (Tchameni et al., 2001).

97         The Ntem complex was affected by two major periods of deformation. The first involves  
98 successive diapiric emplacements of the Mesoarchean charnockites (~ 2.900 Ma) and TTGs (~  
99 2830 Ma). It is marked by vertical foliation and lineation, stretching and isoclinal folds (Shang  
100 et al., 2004a). This episode of deformation was synchronous with a regional granulite-facies  
101 metamorphism (Tchameni, 1997). This Archean event was followed, in the Paleoproterozoic,  
102 by a transcurrent deformation phase marked by the development of N-S to NE-SW trending  
103 sinistral shear zones and partial melting of the TTG suite and the greenstone belt country rocks,  
104 with generation of a variety of granites (Shang et al., 2007). Late syenitic plutons (~ 2.3 Ga)  
105 intruded the complex during this second tectonic episode (Tchameni et al., 2001). The Eburnean  
106 metamorphism affected all the Archean and Paleoproterozoic formations and was dated at ~  
107 2.05 Ga (Toteu et al., 1994).

## 108 **2.2. Local geology and stratigraphy**

109         In the Bikoula region, the BIF ore bodies occur in roughly NW-SE direction with steep  
110 dips 50–80° to the SW or NE (Fig. 2). The main ore body is ~0.5 km in width and extends ~4.8  
111 km along strike. The country rocks in the Bikoula area are pyroxene-bearing granitoids  
112 (charnockites) of various orientations. Observations at outcrops typically reveal highly  
113 weathered BIF with characteristic light (silica) bands alternating with dark (iron oxide) bands  
114 (Fig. 3). Analysis of remote sensing data revealed E-W and NE-SW trending faults/shear zones  
115 that affected both ore bodies and country rocks, resulting in mylonitic structures observed in  
116 many outcrops.

117         A vertical drill core (BKLD030), of ~133.8 m deep, through the central part of the main  
118 ore body (Fig. 2) was chosen for this study. It comprises various iron ore formations cross-cut

119 by syenitic veins (Fig. 4). The lower part of the core comprises unweathered BIF which grades  
120 upwards into partly oxidized and altered sheared BIF. The uppermost part of the sheared BIF  
121 has been affected by weathering and oxidation processes resulting in a sheared oxidized BIF.  
122 Close to the topographic surface, intense weathering and erosional processes prevailed and  
123 generated supergene high-grade ores namely the soft saprolitic and detrital ores. Because the  
124 middle and upper parts of the core were affected by secondary enrichment through intensive  
125 shearing and weathering processes, the present study exclusively focuses on the unweathered  
126 lower part of the drill core.

### 127 **3. Sampling and analytical procedures**

128 Samples were selected from a split diamond core and were then halved using a core  
129 cutting machine (quarter thickness of the whole original core). The length of samples was  
130 variable depending on the scale of banding, the compositional homogeneity and the thickness  
131 of individual rock units. From the sampled quarter, polished thin sections were cut  
132 perpendicular to the banding and the remainder of the core was crushed for geochemical  
133 analyses. A total of 12 unweathered BIF samples and 11 of the syenites were collected for  
134 petrographic and geochemical investigations (Fig. 4).

135 Detailed petrographic observations were undertaken using transmitted and reflected  
136 light microscopy on polished thin sections at ETH Zurich, Switzerland, where a JEOL JXA-  
137 8200 electron microprobe analyzer was utilized for mineral analyses. Natural and artificial  
138 silicates and oxides were used as standards. An acceleration voltage of 15 kV was used, along  
139 with 20 nA beam current and 20  $\mu\text{m}$  beam diameter. Measuring time on the peak was 40  
140 seconds, with 10 seconds on the background. The detection limit was approximately 0.01 wt.%  
141 for major and minor elements, and relative measurement errors did not exceed 1%. A Jeol JSM-  
142 6390 LA scanning electron microscope (SEM), equipped with a secondary electron (SE) and a

143 backscatter electron detector (BSE), was used to examine textural relationships of extremely  
144 fine mineral phases.

145 Major element concentrations in BIF samples were analyzed using an Axios FAST X-  
146 ray fluorescence spectrometer with an RSD (Relative Standard Deviation) < 5% at the ALS  
147 laboratory (Ireland), and in the syenites with a wavelength dispersive X-ray fluorescence  
148 spectrometer (WD-XRF, PANalytical AXIOS) at ETH Zurich. Trace element analyses of BIF  
149 samples were performed using an ICP-MS (Element, Finnigan MAT) at ETH Zurich. Rare earth  
150 elements were acquired using a ThermoFisher XSeries 2 ICP-MS at University of  
151 Southampton. The RSD was < 2.5% for the trace and REE analyses.

## 152 **4. Petrography**

### 153 **4.1. BIF**

154 At the mesoscopic scale, BIF shows a conspicuous banding (Fig. 5a). Banding is  
155 generally irregular in thickness and obliterated in places. The BIF is generally characterized by  
156 intercalated quartz-rich grey-white and magnetite-rich dark bands or laminae. Between these  
157 bands (i.e. light and dark bands), a pyroxene-rich greenish brown layer often occurs, imparting  
158 a greenish coloration to the BIF. Contacts between the laminae are usually diffuse. The  
159 magnetite-rich and pyroxene-rich bands are highly magnetic. The main minerals are quartz (30  
160 – 40 vol.%), magnetite (30 – 50 vol.%) and pyroxene (20 – 30 vol.%), with smaller amounts of  
161 plagioclase, amphibole, biotite, ilmenite and sulfides.

#### 162 **4.1.1. Quartz**

163 Quartz occurs as aggregates in quartz-rich bands or individual grains within the  
164 magnetite- and pyroxene-rich bands, and is often found as inclusions in grains of pyroxene (Fig.  
165 5b). In these bands, quartz occurs as anhedral, up to 2.5 mm in size, slightly elongated grains

166 with moderate preferred orientation (Figs. 5c–d). Quartz is often intermixed with magnetite and  
167 pyroxene, resulting in a weaker banding of the BIF. Many quartz grains exhibit inequigranular  
168 interlobate texture, display undulose extinction and embayed to amoeboid grain boundaries.  
169 Larger grains commonly show patchy extinction resulting from the coalescence of smaller  
170 subgrains. All these deformational features are suggestive of dynamic recrystallization.

#### 171 **4.1.2. Pyroxene**

172 Pyroxene occurs as orthopyroxene and clinopyroxene in approximately equal  
173 proportions. Orthopyroxene is brownish in color, anhedral to subhedral, and forms bands of  
174 variable thickness that appear to alternate with quartz and magnetite bands (Fig. 5b). The  
175 orthopyroxene bands range from 1.5 to 2 mm in thickness and are not continuous, often cross-  
176 cut by magnetite or quartz. Most orthopyroxene occurs as medium to coarse grains up to 4 mm  
177 in length and 2.4 mm wide and often show preferred orientation. The large grains contain  
178 inclusions of clinopyroxene, magnetite and sulfides. Grain boundaries are generally embayed  
179 to smoothly curved against other minerals. Smaller crystals can be found associated with both  
180 the magnetite and quartz-rich laminae. Exsolution lamellae of clinopyroxene as well as  
181 deformation twins are clearly visible in many grains (Fig. 5d).

182 Clinopyroxene is noticeably smaller, reaching 1.5 mm in length for the larger grains,  
183 and occurs as anhedral to subhedral crystals. In thin section, grains appear scattered, are  
184 commonly in contact with magnetite and orthopyroxene bands, and display a preferred  
185 orientation in places. Clinopyroxene is pale green, non pleochroic, with yellow-orange to blue-  
186 purple interference colors, and exhibits straight to curved grain outlines (Fig. 5d). Some  
187 clinopyroxene crystals display simple twinning. Extremely fine orthopyroxene exsolution  
188 lamellae are common in many crystals. Two generations of clinopyroxene occur, the first as

189 porphyroblasts containing exsolution lamellae of orthopyroxene (Fig. 5d) and the second as  
190 small anhedral crystals in large cracks of orthopyroxene megacrysts (Fig. 5e).

### 191 **4.1.3. Magnetite**

192 Magnetite, the main iron mineral of the Bikoula BIF, occurs in 1.5–3.5 mm thick bands.  
193 Within the magnetite-rich layers, magnetite exhibits a texture consisting of continuously  
194 interlocking grains (Figs. 6a–b). Fe-rich layers display many cracks where magnetite is often  
195 partially replaced by pyrite (Fig. 6c). In quartz and pyroxene bands, magnetite grains are  
196 subhedral to euhedral in shape, and may be distributed rather uniformly, or interconnected to  
197 form aggregates of various configurations (see Fig. 5b). Grain boundaries shared with the other  
198 minerals are straight to smoothly curved. Magnetite is also found as inclusions or in contact  
199 with grains of quartz and pyroxene.

### 200 **4.1.4. Minor mineral phases**

201 Sulfides in the Bikoula BIF comprise pyrite, pyrrhotite and subordinate chalcopyrite.  
202 Pyrite occurs as subhedral to euhedral crystals interstitial to magnetite and pyroxene, and  
203 displays straight to smoothly curved contacts with the latter two minerals (Fig. 6a). Pyrite grains  
204 are irregularly shaped with a random arrangement, and may range up to 0.5 mm in size. Most  
205 pyrite crystals are partially to completely replaced by pyrrhotite (Figs. 6c–d), indicating sulphur  
206 release during progressive metamorphism (Craig and Vokes, 1993). Pyrite often contains very  
207 fine inclusions of chalcopyrite and magnetite. Chalcopyrite grains are anhedral to subhedral,  $\leq$   
208 20  $\mu\text{m}$  in size, and commonly associated with pyrite (Fig. 6d).

209 Plagioclase occurs as anhedral to subhedral grains, up to 4 mm, that display undulose  
210 extinction (Figs. 6e–f). It often contains minute inclusions of magnetite. Amphibole forms  
211 strongly pleochroic greenish to brownish colored individual crystals. Mineral grains present  
212 vary from anhedral to subhedral and reach up to 2.8 mm in size. Locally, the mineral is slightly

213 altered to Fe-rich biotite (Fig. 6e), and often contains inclusions of magnetite and plagioclase.  
214 Biotite occurs mostly as aggregates that are bent or kinked, presumably due to tectonic  
215 overprint. Crystals are anhedral to subhedral in shape, and may reach up to 1.6 mm in length.  
216 Some biotite grains are altered to iron-rich biotite (Figs. 6e–f). Ilmenite and ulvöspinel mainly  
217 occur as lamellae in magnetite grains (Fig. 6b). Ilmenite also forms typically  $\leq 0.3$  mm  
218 individual anhedral grains that are associated with magnetite.

## 219 **4.2. Syenites**

220 Syenites (Fig. 7a) are medium- to coarse-grained, grey, and are composed of microcline  
221 (80-90%), plagioclase (3-5%), quartz (2-3%), clinopyroxene (1-3%), magnetite (1-2%), biotite  
222 (1%) and apatite (1%). Accessory phases include ilmenite, pyrite and chalcopyrite. The rock  
223 appears highly strained and recrystallized, mostly along microcline grain margins due to  
224 metamorphism (Figs. 7b–d). Microcline occurs as anhedral, up to 8 mm in length, perthitic  
225 grains with a weak to strong preferred orientation (Figs. 7b–c). Crystals display cross-hatched  
226 twins and, in general, embayment at the grain boundaries. Potassium feldspar crystals are  
227 partially sericitized and host inclusions of magnetite and apatite.

228 Albite phenocrysts, up to 8 mm in size, are commonly anhedral to subhedral with  
229 straight to curved grain outlines, and display undulose extinction (Fig. 7d). Plagioclase  
230 microcrystals and quartz with rare K-feldspar crystals, typically  $\leq 0.1$  mm in size, make up the  
231 fine-grained recrystallized groundmass (Fig. 7e). In the groundmass, quartz is less abundant  
232 than plagioclase. Quartz occurs as anhedral grains that show undulose extinction, commonly  
233 embayed crystal boundaries and rare inclusions of plagioclase and potassium feldspar. Quartz  
234 also fills micro-veinlets that traverse microcline or albite phenocrysts (Fig. 7d).

235 Mafic phases are smaller in size relative to K-feldspar crystals. Clinopyroxene occurs  
236 mainly as subhedral to euhedral grains up to 1.7 mm in length, most of which are isolated and

237 preferentially oriented (Fig. 7c). These grains are usually interstitial between felsic minerals  
238 and rarely occur as inclusions in alkali feldspar megacrysts. The mineral commonly exhibits  
239 sharp and straight to smoothly curved grain boundaries with other minerals and is sometimes  
240 partially altered to anhedral amphibole, chlorite and/or biotite (Figs. 7f–h).

241 Biotite is present as fine-grained (< 0.5 mm in length), subhedral, pleochroic green to  
242 brownish flakes partly altered to chlorite (Fig. 7f). These flakes appear as interstitial isolated  
243 crystals with random orientation and rarely cluster to form aggregates. Biotite often overgrows  
244 or partly replaces clinopyroxene (Figs. 7f and 7i). It commonly shows straight to curved grain  
245 boundaries. All these replacement textures can be ascribed to local manifestations of a  
246 metamorphic overprint.

247 Magnetite and ilmenite form decussate aggregates, often slightly elongated, that are  
248 oriented approximately in the same direction as K-feldspar or pyroxene (Fig. 7j). They also  
249 occur as individual grains within the rock matrix. Crystals are subhedral to euhedral in shape  
250 and may reach up to 0.3 mm and 0.5 mm in length for magnetite and ilmenite, respectively.  
251 Apatite (0.02 to 0.4 mm in length) forms tiny hexagonal, rounded or rectangular grains that  
252 usually occur as inclusions in alkali feldspar, magnetite and pyroxene, or sometimes as isolated  
253 crystals. Pyrite and chalcopyrite were observed within the groundmass of the syenites or as  
254 inclusions in pyroxene.

## 255 **5. Geochemistry**

### 256 **5.1. Mineral chemistry**

#### 257 **5.1.1. Magnetite**

258 Electron microprobe analyses of magnetite in the Bikoula BIF show that the magnetite  
259 has total iron content (expressed as FeO<sub>t</sub>) between 92.06 and 93.98 % (Table 1). In contrast to

260 magnetite from typical BIFs found in other regions worldwide (Dupuis and Beaudoin, 2011), it  
261 has high Al<sub>2</sub>O<sub>3</sub> (0.18 to 0.59 %, average 0.34 %) and TiO<sub>2</sub> (0.09 to 0.56 %, average 0.21 %). In  
262 syenites (Appendix A.1), magnetite shows FeO<sub>t</sub> content as high as in BIF (average 92.99 %),  
263 but is highly depleted in all the other elements.

### 264 **5.1.2. Clinopyroxene**

265 Clinopyroxene in syenites is diopsidic in composition (~Wo<sub>40-42</sub>En<sub>27-28</sub>Fs<sub>19-22</sub>) with  
266 minor aegirine and jadeite component (~3.4–8.7 and ~0–4.3 mol.%, respectively) and has X<sub>Fe</sub>  
267 (Fe<sup>2+</sup>/Mg+Fe<sup>2+</sup>) of ~0.41–0.45 (Fig. 8a, Appendix A.2). Clinopyroxene in the BIF is more iron  
268 rich and reaches less calcic and sodic compositions (Appendix B.1, Fig. 8a). The composition  
269 ranges from diopside (~Wo<sub>43</sub>En<sub>28</sub>Fs<sub>29</sub>) to augite (~Wo<sub>37</sub>En<sub>26</sub>Fs<sub>22</sub>) and with lower aegirine and  
270 jadeite contents (~3.6–7.1 and ~0–1.2 mol.%, respectively) and more FeO<sub>t</sub> (X<sub>Fe</sub> ~0.46 – 0.51)  
271 compared to the clinopyroxene in syenites.

### 272 **5.1.3. Orthopyroxene**

273 Orthopyroxene electron probe microanalyses are tabulated in Appendix B.2. Compared  
274 to the clinopyroxenes, the orthopyroxene is more iron-rich (Wo<sub>1.2-1.6</sub>En<sub>34-36</sub>Fs<sub>59-62</sub>) (Fig. 8a)  
275 with significant concentrations of CaO and MnO (0.58 – 0.75 % and 1.23 – 1.55 %, respectively).  
276 Orthopyroxene grains have low Al<sub>2</sub>O<sub>3</sub> and Cr<sub>2</sub>O<sub>3</sub> contents (< 0.19 %) and high  
277 X<sub>Fe</sub> (> 0.6).

### 278 **5.1.4. Amphibole**

279 The calculation of crystal formula for amphiboles shows the following characteristics:  
280 (Ca+Na)<sub>B</sub> = 1.597–1.789 (≥ 1); Ca<sub>B</sub> = 1.597–1.789 (≥ 1.5); Si = 6.341–6.470; Ti = 0.112–0.137  
281 (< 0.5); (Na+K)<sub>A</sub> = 0.910–0.999 (≥ 0.5) and Mg# = 0.455–0.471 (Appendix B.3). According to

282 the international nomenclature of amphiboles (Leake et al., 1997), it classifies as ferro-pargasite  
283 (Fig. 8b), a member of the calcic group of amphiboles.

#### 284 **5.1.5. Feldspar**

285 Feldspar in the syenites (Appendices A.3 and A.4) is dominated by perthitic microcline  
286 (orthoclase > 96 %) exsolving albite (An = 5.4–8.6 %). Feldspar in the BIF is a plagioclase of  
287 oligoclase composition (An = 17.0–19.7 %) and relatively homogeneous in chemical  
288 composition (Appendix B.4).

#### 289 **5.1.6. Biotite**

290 In the BIF, biotite is characterized by  $X_{\text{Fe}} = 0.452\text{--}0.487$ ,  $\text{Al}^{\text{IV}} = 1.076\text{--}1.120$ ,  $\text{Mg}\# =$   
291  $0.513\text{--}0.548$  and  $\text{Ti} = 0.216\text{--}0.256$  (Appendix B.5). Alteration-type biotite shows higher iron  
292 contents and is depleted in  $\text{TiO}_2$ .

#### 293 **5.1.7. Ilmenite**

294 Major element analyses for ilmenite show  $\text{TiO}_2$  of 50.17 – 51.32 % in syenites and of  
295 51.06 – 52.05 % in BIF (Appendices A.5 and B.6). Ilmenite in BIF has lower  $\text{FeO}_t$  than ilmenite  
296 in syenites (average 40.88 % compared to 43.83 %, respectively), while average MnO is higher  
297 (7.02 % in BIF compared to 4.38 % in syenites).

### 298 **5.2. Bulk rock geochemistry**

#### 299 **5.2.1. BIF**

300 Major and trace element data of the BIF samples are listed in Table 2. The  $\text{Fe}_2\text{O}_3$  content  
301 varies from 42.79 to 57.89 wt.% (average 49.97 wt.%),  $\text{SiO}_2$  32.3 to 42 wt.% (average 37.77  
302 wt.%) and  $\text{Al}_2\text{O}_3$  0.76 to 7.52 wt.% (average 2.88 wt.%) (Table 2). The contents of other major  
303 oxides are also quite significant, i.e. CaO 1.95 – 4.90 wt.%,  $\text{K}_2\text{O}$  0.13 – 1.96 wt.%,  $\text{Na}_2\text{O}$  0.19

304 – 2.05 wt.% and MgO 3.78 – 5.59 wt.%. The BIF is also characterized by low contents of TiO<sub>2</sub>  
305 (0.11 – 0.88 wt.%), MnO (0.39 – 0.56 wt.%) and P<sub>2</sub>O<sub>5</sub> (0.09 – 0.13 wt.%).

306 Variations in some transition elements are as follows; V 7.58 – 49.56 ppm, Cr 8 – 225.67  
307 ppm, Ni 5.05 – 84.63 ppm, Cu 3.07 – 32.27 ppm and Zn 55.32 – 150.71 ppm. Among the High  
308 Field Strength Elements (HFSE), Y, Zr and Sc vary from 10.99 – 28.99 ppm, 7.44 – 111.46  
309 ppm and 0.78 – 6.19 ppm, respectively (Table 2). The contents of Large Ion Lithophile  
310 Elements (LILE; Rollinson, 1993) Rb, Sr and Ba vary from 5.09 to 153.73 ppm, 21.45 to 210.09  
311 ppm and 16.82 to 200.46 ppm, respectively. Mo abundances are low (< 6 ppm, Table 2) as  
312 expected in older BIFs (Stern et al., 2013; Scott et al., 2008).

313 Samples analyzed from the Bikoula BIF show variable REE contents with  $\Sigma$ REE  
314 ranging from 8.90 to 111.54 ppm (Table 2). All the samples are characterized by high LREE  
315 relative to HREE (LREE/HREE ranges from 5.06 and 19.69). PAAS-normalized REE-Y  
316 patterns (Fig. 9) show depletion of LREE ( $La/Yb_{PAAS} < 1$ ) except in one sample (i.e. sample  
317 L271), strong positive Y anomalies ( $Y/Y^*_{PAAS} = 0.98 – 6.25$ ) and weak negative Ce anomalies  
318 ( $Ce/Ce^*_{PAAS} = 0.85 – 0.99$ ). Of the twelve BIF samples analyzed, five display strongly positive  
319 Eu anomalies ( $Eu/Eu^*_{PAAS} = 1.19 – 3.45$ ), another five display slightly negative Eu anomalies  
320 (0.58 – 0.86) while two do not show any anomaly (samples L273 and L282).

### 321 **5.2.2. Syenites**

322 Whole-rock compositions of the studied syenites are presented in Table 3. SiO<sub>2</sub> contents  
323 range from 58.29 to 65.73 wt.%, Al<sub>2</sub>O<sub>3</sub> 15.29 to 18.91 wt.% and Fe<sub>2</sub>O<sub>3</sub> 1.15 to 7.82 wt.%. K<sub>2</sub>O  
324 and Na<sub>2</sub>O contents are relatively high and similar, both varying between 4.83 and 7.07 wt.%  
325 (Table 3). There are significant contents of CaO (0.76 – 3.30 wt.%; average 1.59 wt.%) and  
326 MgO (0.22 – 1.32 wt.%; average 0.69 wt.%). Other major oxide components are minor in  
327 abundance, namely TiO<sub>2</sub> (0.02 – 0.74 wt.%), P<sub>2</sub>O<sub>5</sub> (0.03 – 0.50 wt.%) and MnO (0.02 – 0.13

328 wt.%). On the total alkali ( $\text{Na}_2\text{O}+\text{K}_2\text{O}$ ) vs. silica diagram (Cox et al., 1979), the syenites plot  
329 in the alkaline fields (syenite and nepheline syenite fields, Fig. 10).

## 330 **6. Discussion**

### 331 **6.1. Mineral paragenesis and effects of metamorphism**

332 The major mineral assemblage of the Bikoula BIF is magnetite-quartz-orthopyroxene-  
333 clinopyroxene (see Fig. 5). This mineralogy, which was observed in all samples, is  
334 characteristic of iron formations that have undergone granulite-facies metamorphism (Klein,  
335 2005). As mentioned in section 2.1, the Ntem complex experienced multiple phases of  
336 deformation and metamorphism. Thus, the two generations of clinopyroxene identified in the  
337 BIF (see Figs. 5d–e), the presence of secondary biotite (see Figs. 6e–f), and the retrogressive  
338 reaction textures in the cross-cutting syenites likely result from multistage metamorphism with  
339 regressive post-peak events.

340 In general, exsolution lamellae in pyroxene occur in many igneous and metamorphic  
341 rocks as the result of slow cooling from the highest equilibration temperature. This unmixing  
342 phenomenon is usually a fossil indicator of very high temperature prevailing during  
343 crystallization. Exsolution lamellae in ortho- and clinopyroxene are commonly reported in  
344 high-grade metamorphosed BIFs, resulting either from contact metamorphism (e.g.,  
345 Bonnischen, 1969, 1975; Vaniman et al., 1980) or regional metamorphism (e.g., Sandiford and  
346 Powell, 1986a; Gole and Klein, 1981; Harley, 1987; Bhattacharya et al., 1990; Fonarev et al.,  
347 2006). Outcrop observation, petrographic analysis and bulk rock composition have shown that  
348 the Bikoula iron occurrences are typical of sedimentary banded iron formations (BIFs). The  
349 assemblages of the Bikoula BIF do not have hornfelsic textures. Rather, existing studies  
350 exclusively point to a regional high-grade metamorphism that prevailed during or soon after  
351 emplacement of charnockite (Toteu et al., 1994; Tchameni et al., 2000; Pouclet et al., 2007).

352 Thus, despite the close spatial relationship between the greenstones and charnockitic country  
353 rocks (see Figs. 1 and 2), the metamorphic assemblages in the Bikoula BIF are most likely not  
354 the result of contact metamorphism. The peak of the regional metamorphism was constrained  
355 at  $750\text{ }^{\circ}\text{C} \pm 50\text{ }^{\circ}\text{C}$  and 5 – 6 Kb (Tchameni, 1997). Therefore, exsolution textures in the Bikoula  
356 BIF may likely result from a regional granulite-facies metamorphism affecting the greenstones  
357 and magmatic rocks of the Ntem complex.

358 In the currently observable assemblage, magnetite is the dominant Fe-rich mineral of  
359 the Bikoula BIF. Due to the high metamorphic degree and the recrystallized habit of the  
360 magnetite crystals, it is not possible to precisely link the evolution of this mineral to the primary  
361 process of iron precipitation from seawater. As proposed in many models for BIF formation,  
362 the primary iron mineral that precipitated directly from seawater was most likely a  $\text{Fe}^{3+}$   
363 oxyhydroxide, a mixed valence Fe-silicate or a  $\text{Fe}^{2+}$ -carbonate (e.g., ferrihydrite, greenalite, and  
364 siderite) (Fischer and Knoll, 2009). Studies of low grade metamorphosed BIF indicates that  
365 such primary minerals commonly transform through a large variety of possible abiotic or  
366 microbially mediated process into magnetite, hematite, iron carbonates (siderite and ankerite),  
367 and various iron-silicate phases (Posth et al., 2013; Smith et al., 2013; Bontognali et al., 2013).  
368 Therefore, the magnetite present in the Bikoula BIF may be a recrystallized diagenetic product  
369 or, alternatively, it may have formed during a later metamorphic process during which one of  
370 the abovementioned primary or diagenetic phase (e.g., siderite, ankerite, Fe-silicate) was  
371 transformed into magnetite.

372 Fukada et al. (2001) proposed that Ti in magnetite from the Superior-type BIF in the  
373 Hamersley basin may have originated from hydrothermal solutions, while Ti in silicates was  
374 introduced from terrigenous sources. Such explanation for the origin of Ti may also apply to  
375 the Bikoula BIF. Ti may have reacted with magnetite during metamorphism to form a Ti-  
376 bearing magnetite. Depending on the oxygen fugacity during the cooling process that followed

377 the peak of metamorphism, some Ti-rich magnetite grains may have been oxidized to ilmenite  
378 lamellae while the un-oxidized portions exolved ulvöspinel (Simmons et al., 1974).

379 Quartz occurs as inclusions in pyroxene, suggesting that it was a phase that crystallized  
380 early. Quartz in iron formations is regarded as resulting from recrystallization of initial  
381 amorphous silica precipitate (i.e., chert) during metamorphism (Klein, 2005). In the Bikoula  
382 BIF, textural analysis revealed that quartz was most likely dynamically recrystallized through  
383 bulging, subgrain rotation and grain boundary migration, suggesting its crystallization during  
384 prograde metamorphism (Passchier and Trouw, 2005).

385 Metamorphic Al-bearing phases in the Bikoula BIF comprise of ferro-pargasite, bitotite  
386 and oligoclase. Oligoclase inclusions in ferro-pargasite suggest that the latter crystallized after  
387 plagioclase. Ferro-pargasite is considered as the product of the reaction between Al-rich clastic  
388 material in the BIF and a Ca-Mg-Fe bearing silicate precursor during prograde metamorphism  
389 (Wang et al., 2014).

390 Banding in iron formations may exist on a range of scales: macrobands (meter thick  
391 rock types), mesobands (centimeter in thickness) and microbands (millimeter to sub-millimeter)  
392 (Trendall and Blockley, 1970). Explanations for banding in BIF include microbial blooms  
393 (Trendall and Blockley, 1970), silica precipitation interrupted by pulses of Fe-rich waters  
394 (Hamade et al., 2003), density flow deposition (Lascelles, 2007), temperature fluctuation in the  
395 oceanic photic zone (Posth et al., 2008), internal dynamics of the geochemical system (Wang  
396 et al., 2009), and episodic re-sedimentation of Fe-silicates alternating with periods of non-  
397 deposition (Rasmussen et al., 2013). Due to the extensive recrystallization that occurred during  
398 metamorphism, it would be too speculative to propose any hypothesis regarding the origin of  
399 banding in the Bikoula BIF. In the studied core, it is even difficult to conclude whether some

400 of the laminations correspond to primary sedimentary layers or represent a banding of purely  
401 metamorphic origin.

## 402 **6.2. Detrital input into BIF**

403 Banded iron formations have long been considered as chemically precipitated  
404 sediments. However, many authors agree that, in several cases, precipitation and accumulation  
405 of chemical sediments was influenced by the simultaneous deposition of detrital components  
406 (Arora et al., 1995; Horstmann and Hälbich, 1995; Basta et al., 2011; Kato et al., 1996; Bolhar  
407 et al., 2005b; Sunder Raju, 2009). Elevated  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$  are considered as indicators of  
408 detrital influx during BIF deposition. Similarly, Si, Mg, Ca and K are thought to be commonly  
409 present in detrital sediments (Hatton and Davidson, 2004). Thus, the relatively high abundance  
410 of  $\text{Al}_2\text{O}_3$  (0.76 – 7.52 wt.%),  $\text{TiO}_2$  (0.11 – 0.88 wt.%), MgO (3.78 – 5.59 wt.%), CaO (1.95 –  
411 4.90 wt.%),  $\text{K}_2\text{O}$  (0.13 – 1.96 wt.%) and  $\text{Na}_2\text{O}$  (0.19 – 2.05 wt.%) suggest detrital influx during  
412 deposition of the Bikoula BIF. Furthermore,  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$  vary sympathetically, with a  
413 correlation coefficient  $R^2 = 0.34$  (see Table 4), suggesting incorporation of detrital components  
414 to the chemical precipitate (González et al., 2009; Pecoits et al., 2009; Lan et al., 2014). Clastic  
415 contamination of the Bikoula BIF is further supported by a plot of  $\text{Y}/\text{P}_2\text{O}_5$  as a function  $\text{Zr}/\text{Cr}$   
416 (Marchig et al., 1982). On this diagram, the samples plot either in the deep-sea sediment field  
417 or between the latter and the hydrothermal field (Fig. 11).

418 Trace elements such as Zr, Hf, Y, Rb and Sr are commonly derived from weathering of  
419 crustal felsic rocks, whereas Cr, Ni, Co, V and Sc commonly have a mafic source (Rao and  
420 Naqvi, 1995). Table 4 displays significant positive correlations of  $\text{Al}_2\text{O}_3$  with LILEs, HFSEs  
421 and transition metals. The correlation coefficients ( $R^2$ ) are:  $\text{Al}_2\text{O}_3$  vs. V ( $R^2 = 0.50$ ), vs. Ni  
422 (0.39), vs. Zn (0.42), vs. Sc (0.44), vs. Y (0.41), vs. Zr (0.53), vs. Th (0.65), vs. U (0.58), vs.  
423 Pb (0.97), vs. Rb (0.73), vs. Sr (0.41) and vs. Ba (0.46) (Table 4). All these relationships may

424 indicate involvement of clastic materials and further suggest that this detritus might have been  
425 derived from weathering of both felsic and mafic (bimodal) sources.

426         The Th/U ratio can also be used to trace the sources of contaminants in BIF. Possible  
427 syn-depositional contaminants of iron formations include volcanic ash, sedimentary detritus  
428 and material of uncertain origin such as phosphate grains (Thurston et al., 2012). Phosphate  
429 contamination is generally associated to a Th/U > 5 (Thurston et al., 2012), while other  
430 contaminants (i.e. clastic or volcanic) have Th/U ratios of ca. 3 – 5 (Condie, 1993; Thurston et  
431 al., 2012). Thus, the incorporation of phosphates in iron formation raises the Th/U ratio. In the  
432 Bikoula BIF samples, the Th/U ratio lies between 2.93 and 6.92 (average 4.44), indicating little  
433 or no phosphate contamination. Zr contents vary sympathetically with the Th/U ratios ( $R^2 =$   
434 0.61, Table 4), consistently with clastic contamination.

### 435 **6.3. Sources of chemical components**

436         Several discrimination diagrams have been used by many workers to constrain the  
437 influence of seawater, hydrothermal, biologic and detrital sources on BIF genesis (e.g., Wonder  
438 et al., 1988; Stern et al., 2013; Xu et al., 2014). On the Fe-Mn-Al diagram (Bonatti et al., 1979),  
439 the Bikoula BIF samples fall in the hydrothermal field (Fig. 12). Similarly, the Al<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub>  
440 discrimination diagram (Wonder et al., 1988) shows that most of the BIF samples plot in the  
441 hydrothermal field (Fig. 13). This may indicate that Si and Fe were likely derived from  
442 hydrothermal sources. However, two samples plot in the hydrogenous field (Fig. 13),  
443 suggesting chemical precipitation from seawater with insignificant hydrothermal input. The  
444 seawater input is also suggested by the low CaO/(CaO+MgO) ratios ranging from 0.31 to 0.53  
445 (Table 2), indicative of sediments that precipitated from seawater (Dasgupta et al., 1999).

446         Bostrom (1973) described a method for assessing dilution by clastic or volcanic detritus  
447 of hydrothermal/hydrogenous input and proposed a plot of Fe/Ti versus Al/(Al+Fe+Mn) to

448 quantify the hydrothermal input relative to the detrital component. Aluminum and titanium  
449 cannot be introduced in solution (Ewers and Morris, 1981) and are immobile during  
450 hydrothermal, diagenetic and weathering processes (Kato et al., 1996). These two elements can  
451 thus be used as proxies to quantify clastic input. Fe and Mn are enriched in components of  
452 hydrothermal fluids (Gurvich, 2006), and therefore serve as hydrothermal proxies. Pure  
453 hydrothermal sediments are characterized by high Fe/Ti ratio ( $> 7000$ ) while pure clastic  
454 sediments are enriched in Al resulting in  $Al/(Al+Fe+Mn) > 0.6$  (Peter and Goodfellow, 1996;  
455 Hatton and Davidson, 2004). On the  $Al/(Al+Fe+Mn)$  diagram of Bostrom (1973), the Bikoula  
456 BIF samples plot within or close to the field of hydrothermal Soldier Cap Group iron formations  
457 (Hatton and Davidson, 2004) and far from the region occupied by modern pelagic-terrigenous  
458 sediments (Fig. 14). Figure 14 also suggests quite significant contribution of hydrothermal  
459 processes (over 70 vol.%) to the deposition of the Bikoula BIF.

460 Positive correlations between  $Al_2O_3$  or  $TiO_2$  versus  $Na_2O$ ,  $K_2O$ ,  $MgO$  and  $CaO$  (see  
461 Table 4) suggest a common origin for these elements, which were likely present in detrital  
462 particles.

463 Measurements of rare earth elements (REE) in BIFs have often been used to infer the  
464 chemical evolution of early oceans and, in particular, to detect the influx of submarine  
465 hydrothermal emanations within the basin-waters from where BIFs were precipitated (Derry  
466 and Jacobsen, 1990; Bau and Möller, 1993; Kato et al., 1998). Indeed, REE are only minimally  
467 fractionated during adsorption onto ferric iron oxyhydroxides precipitates (Bekker et al., 2014)  
468 and, due to closed-system conditions for the REE and low fluid/rock ratios, the REE distribution  
469 is usually not affected in BIFs that have undergone low- to high-grade regional or contact  
470 metamorphism (Bau, 1993). Petrographic analyses suggest that the Bikoula BIF samples  
471 studied have experienced high-grade metamorphism with only minor infiltration metasomatism  
472 and, therefore, may record quite original REE signals. PAAS-normalized REE-Y patterns (Fig.

473 9) show that some BIF samples have preserved seawater-like features such as LREE depletion,  
474 and positive La and Y anomalies (Alibo and Nozaki, 1999; Bolhar et al., 2004), which points  
475 to precipitation from seawater.

476 Positive Eu anomalies in BIFs have been interpreted as evidence that submarine  
477 hydrothermal fluids –that may be source not only of the REE but also of Fe and Si– were  
478 important component of the solution from where the Fe-minerals were precipitated (Derry and  
479 Jacobsen, 1990; Slack et al., 2007). In the Bikoula BIF, five samples display positive Eu  
480 anomalies ( $\text{Eu}/\text{Eu}^*_{\text{PAAS}} = 1.19 - 3.45$ ), pointing to fluxes of high-temperature ( $> 350^\circ\text{C}$ )  
481 hydrothermal fluids. However, seven samples display no or weakly negative Eu anomalies (Fig.  
482 9). The negative Eu anomaly (rarely seen in BIFs) suggests that REE patterns in the Bikoula  
483 BIF were also influenced by the heterogeneous input of clastic materials within the depositional  
484 basin (Arora et al., 1995; Manikyamba et al., 1993; Manikyamba and Naqvi, 1997b).

485 Dymek and Klein (1988) and subsequently Alexander et al. (2008) introduced  
486 conservative two component mixing diagrams to assess the proportions of seawater and high-  
487  $T$  hydrothermal fluids. According to the Sm/Yb-Eu/Sm and Y/Ho-Eu/Sm diagrams (Figs. 15a  
488 and b, respectively), extremely small amounts of submarine high- $T$  hydrothermal fluids ( $< 0.1$   
489 %) were enough to cause positive Eu anomalies in the Bikoula BIF. Therefore, as observed in  
490 other BIFs, it can be deduced that relatively small inputs of high- $T$  hydrothermal fluids may  
491 have been sufficient to account for REE-Y distribution in the Bikoula BIF.

#### 492 **6.4. Redox state of ocean water at the time of the Bikoula BIF deposition**

493 Ce concentrations in BIFs provide information helpful for constraining paleoredox  
494 conditions of ancient seawater. In general, modern oxygenated marine settings show a strong  
495 negative Ce anomaly when normalized to shale compositions. This arises from the oxidation of  
496  $\text{Ce}^{3+}$  to  $\text{Ce}^{4+}$  and incorporation into Fe-Mn oxyhydroxides, clay particles and organic matter

497 (Byrne and Sholkovitz, 1996). In contrast, suboxic and anoxic marine waters lack large Ce  
498 anomalies as a result of reductive dissolution of the Fe-Mn particles (German et al., 1991).  
499 However, it can be challenging to identify Ce anomalies because of anomalous abundances of  
500 La. Bau and Dulski (1996) proposed a discrimination diagram that compares  $(Ce/Ce^*)_{SN}$   
501 calculated as  $Ce_{SN}/(0.5La_{SN} + 0.5Pr_{SN})$  to  $(Pr/Pr^*)_{SN}$  calculated as  $Pr_{SN}/(0.5Ce_{SN} + 0.5Nd_{SN})$  to  
502 identify ‘real’ La and Ce anomalies in BIFs. As it is the case with other Archean and early  
503 Paleoproterozoic BIFs (Planavsky et al., 2010), the Bikoula BIF samples lack negative Ce  
504 anomalies (Fig. 16). The lack of evidence for Ce oxidation (implying that the reservoir of  $Fe^{2+}$   
505 is not fully oxidized) is consistent and supports the commonly held view that, during the  
506 Mesoarchean, oceans were (at least partly) anoxic or suboxic, allowing for the transport and  
507 accumulation of  $Fe^{2+}$  (Lyon et al., 2014). Under these conditions, various mechanisms may  
508 have caused the progressive mineralization of the  $Fe^{2+}$  reservoir, leading to the formation of the  
509 Bikoula BIF, including: oxidation with  $O_2$  produced by photosynthetic microbes or oxidation  
510 through abiotic photochemical reactions (Cairns-Smith, 1978), microbial oxidation through  
511 anoxygenic photosynthesis (Widdel et al., 1993), or even through direct precipitation from  
512 anoxic seawater as ferrous or mixed valences minerals (e.g., siderite, iron-rich clay minerals)  
513 (Rasmussen et al., 2014).

## 514 **Conclusion**

515 The Bikoula BIF is located within the Mesoarchean Ntem complex, South Cameroon,  
516 and it is included in a ~3.1 Ga greenstone belt hosted by charnockitic granites. The BIF  
517 sequence is locally cross-cut by late syenitic veins.

518 Petrographic analysis revealed that the BIF mainly consists of magnetite, quartz,  
519 orthopyroxene and clinopyroxene. BIF suffered high-grade metamorphism that caused intense  
520 recrystallization of precursor precipitates. The presence of minor amounts of Al-rich phases

521 (ferro-pargasite, biotite and oligoclase) and high contents of Al<sub>2</sub>O<sub>3</sub>, TiO<sub>2</sub>, Na<sub>2</sub>O, K<sub>2</sub>O, MgO and  
522 CaO suggest that the primary chemical precipitate was contaminated by a significant amount  
523 of clastic material.

524 REE-Y patterns of the Bikoula BIF display positive Eu anomaly, which indicates that  
525 seawater from which the BIF precipitated was influenced by hydrothermal solutions. In some  
526 samples, Eu anomalies are very low or even slightly negative, likely as the result of variable  
527 amount of clastic contamination. Finally, the lack of Ce anomalies in the studied BIF suggests  
528 that its deposition occurred in a basin that was not fully oxic (i.e., at least partly anoxic or  
529 suboxic), where it was possible to transport and concentrate dissolved Fe<sup>2+</sup>.

### 530 **Acknowledgments**

531 This paper is an integral part of the first author's Ph.D thesis at the University of  
532 Yaoundé 1 (Cameroon). The authors thank Aluvance Plc for permission to sample diamond  
533 drill core from the Bikoula Iron Ore Project, and providing technical data on the project. Much  
534 thanks to its VP Operations, Jonathan Hunt, for assistance during field work. Daniela Hunziker  
535 and Lukas Martin are gratefully acknowledged for invaluable assistance in microprobe analysis.  
536 We also thank Remy Luechinger for the preparation of polished thin sections, and the two  
537 anonymous reviewers for constructive comments that helped to improve an earlier manuscript  
538 version. This project was financially supported by the Swiss Government Excellence  
539 Scholarships and the Department of Earth Sciences of ETH Zurich. J.V. acknowledges the ERC  
540 starting grant (335577) of L. Tajcmanova for financial support.

## 836 **Table captions**

837 **Table 1.** Electron microprobe analyses of magnetite from the Bikoula BIF.

838 **Table 2.** Major (wt.%) and trace (ppm) element contents in the Bikoula BIF.

839 **Table 3.** Major element contents (wt.%) in syenites.

840 **Table 4.** Linear inter-element correlations ( $R^2$ ) for all BIF samples ( $n = 12$ ).

841 **Appendix A.** Electron microprobe analyses of minerals in syenites.

842 **A.1.** Magnetite

843 **A.2.** Clinopyroxene

844 **A.3.** Microcline

845 **A.4.** Albite

846 **A.5.** Ilmenite

847 **Appendix B.** Electron microprobe analyses of minerals from the Bikoula BIF.

848 **B.1.** Clinopyroxene

849 **B.2.** Orthopyroxene

850 **B.3.** Ferro-pargasite

851 **B.4.** Oligoclase

852 **B.5.** Biotite

853 **B.6.** Ilmenite

854

855 **Figure captions**

856 **Fig. 1.** Geological map of SW Cameroon (modified after Pouclet et al., 2007). The star indicates  
857 the position where the studied BIF occurs.

858 **Fig. 2.** Geological map showing the location where the core intersecting the studied BIF was  
859 drilled.

860 **Fig. 3.** Field photos of the Bikoula BIF. (a and b) Weathered outcrops of BIF occurring in the  
861 study area. (c) Hand sample collected from an outcrop, showing dark iron-rich bands and light  
862 quartz-rich bands as well as yellowish goethite or limonite resulting from supergene  
863 weathering.

864 **Fig. 4.** Stratigraphy of the Bikoula BIF with sample locations.

865 **Fig. 5.** Core section (a) and photomicrographs (b–e) of the Bikoula BIF, (c) and (d) taken with  
866 crossed polars. (a) Unweathered BIF drill core sample showing black Fe-rich bands alternating  
867 with whitish silica bands and greenish silicate bands. (b) BIF consisting of alternating magnetite

868 (Mag), quartz (Qtz) and pyroxene (Opx and Cpx) bands. (c) BIF showing magnetite, pyroxene  
869 and quartz bands; some quartz grains show preferred orientation and are dynamically  
870 recrystallized. (d) BIF showing pyroxene exsolution textures; orthopyroxene (Opx) exsolving  
871 clinopyroxene (Cpx) lamellae and first generation of clinopyroxene (Cpx<sup>I</sup>) exsolving Opx  
872 lamellae. (e) Photomicrograph showing later generation of clinopyroxene (Cpx<sup>II</sup>) developed in  
873 the interstices of large Opx grains. Mineral abbreviations according to Whitney and Evans  
874 (2010).

875 **Fig. 6.** Photomicrographs and SEM image of the Bikoula BIF; red arrows indicate  
876 alteration/replacement texture. (a) Reflected light photomicrograph illustrating magnetite band  
877 with cracks; pyrite (Py) grains are associated with magnetite. (b) SEM image illustrating  
878 interlocking magnetite grains containing ilmenite (Ilm) and ulvöspinel (fine, dark) lamellae. (c)  
879 Reflected light photomicrograph of pyrite and magnetite; pyrite replaces magnetite along  
880 cracks. (d) Reflected light photomicrograph of pyrite, pyrrhotite (Po) and chalcopyrite (Ccp);  
881 pyrrhotite replaces pyrite. (e–f) Cross polarized light photomicrograph of BIF consisting of  
882 oligoclase (Olg), ferro-pargasite (Fp), magnetite, biotite (Bt) and iron-rich biotite; iron-rich  
883 biotite (Fe-Bt) occurs as alteration phase which replacing ferro-pargasite or biotite as shown  
884 with red arrows.

885 **Fig. 7.** Petrographic characteristics of the syenites intercalated with the BIF, red arrows indicate  
886 alteration/replacement textures. (a) Drill core sample showing macroscopic features. (b–c)  
887 Syenite consisting of microcline (Mc) and clinopyroxene in a fine recrystallized groundmass;  
888 grains show a preferred orientation. (d) Albite (Ab) and microcline phenocrysts surrounded by  
889 groundmass; groundmass fills interstices and fractures of phenocrysts. (e) Groundmass  
890 consisting of quartz, polysynthetic twinned plagioclase and k-feldspar (Kfs). (f)  
891 Photomicrograph showing chlorite (Chl) replacing biotite (left red arrow) and biotite and  
892 chlorite replacing clinopyroxene (right red arrow) (Plane polarized light). (g–h) Plane polarized

893 light (g) and crossed polarized light (h) photomicrographs showing replacement reaction texture  
894 of clinopyroxene by amphibole (Amp) and chlorite. (i) Photomicrograph of syenite consisting  
895 of microcline, clinopyroxene, biotite and magnetite-ilmenite aggregate; biotite overgrowths  
896 clinopyroxene. (j) Magnetite-ilmenite aggregates, preferentially oriented; note some fine  
897 rounded apatite grains (Reflected light microscopy).

898 **Fig. 8.** (a) Compositional ranges of pyroxenes (Morimoto et al., 1989) including clinopyroxene  
899 in syenite, clinopyroxene and orthopyroxene in BIF. (b) Amphibole compositions (diamonds)  
900 plotted on Si vs. Mg# diagram (Leake et al., 1997).

901 **Fig. 9.** PAAS-normalized REE-Y patterns of the Bikoula BIF. Seawater data: average of 0, 9  
902 and 30 m depth samples of station SA-5 (Zhang and Nozaki, 1996).

903 **Fig. 10.** Compositions of the syenites (black diamonds) plotted in a total alkalis vs. silica (TAS)  
904 diagram (after Cox et al., 1979).

905 **Fig. 11.** Compositions of the Bikoula BIF plotted in a bivariate diagram of  $Y/P_2O_5$  vs.  $Zr/Cr$ .  
906 Deep-sea, diagenetic and metalliferous fields are based on data from Marchig et al. (1982).

907 **Fig. 12.** Ternary Fe–Mn–Al plot showing hydrothermal and non-hydrothermal fields for  
908 modern marine ferromanganese deposits (Bostrom, 1973). The Bikoula BIF plots within the  
909 hydrothermal field. Fields for metalliferous sediments from the East Pacific Rise (EPR)  
910 (Bostrom, 1973), Deep Sea Drilling Project (DSDP) Leg 31 (Bonatti et al., 1979), Cyprus  
911 umbers (Robertson and Hudson, 1973) and other oceanic sediments are also included.

912 **Fig. 13.** Plot of  $Al_2O_3$  vs.  $SiO_2$  (after Wonder et al., 1988) to illustrate the origin of primary  
913 chemical precipitates of the Bikoula BIF samples (Filled triangles).

914 **Fig. 14.** Composition of the Bikoula BIF (Filled triangles) plotted on the Fe/Ti vs.  
915  $Al/(Al+Fe+Mn)$  discrimination diagram (after Bostrom, 1973). This diagram is proposed for

916 estimating the relative contribution from hydrothermal inputs in the fluid from where BIF  
917 precipitated. Hydrothermal chemical sediment of the Soldier Cap Group iron formations  
918 (Hatton and Davidson, 2004) is plotted to show the hydrothermal input.

919 **Fig. 15.** Composition of the Bikoula BIF (triangles) plotted in an elemental ratio diagram with  
920 two-component conservative mixing lines for Eu/Sm, Sm/Yb, and Y/Ho (after Alexander et al.,  
921 2008). The high- $T$  ( $>350^{\circ}\text{C}$ ) hydrothermal fluids follow Bau and Dulski (1999) and the Pacific  
922 seawater follow Alibo and Nozaki (1999). (a) Plot of Sm/Yb vs. Eu/Sm showing a  $\leq 0.1\%$  high- $T$   
923 hydrothermal fluid contribution. (b) Plot of Y/Ho vs. Eu/Sm showing a  $\leq 0.1\%$  high- $T$   
924 hydrothermal fluid contribution.

925 **Fig. 16.** Composition of the Bikoula BIF plotted in a  $(\text{Ce}/\text{Ce}^*)_{\text{SN}}$  vs.  $(\text{Pr}/\text{Pr}^*)_{\text{SN}}$  diagram after  
926 Bau and Dulski (1996).
